Keywords: laser direct deposition; 30Cr3Ni2 alloy steel; microstructure; hardness; granular bainite.

Abstract: 30Cr3Ni2 alloy steel was prepared by laser direct deposition technology. The microstructures and hardness of the alloy steel were studied by metallurgical microscope, scanning electron microscope, energy dispersive spectrometer, X-ray diffraction, microhardness tester and transmission electron microscope. The results show that the microstructure of 30Cr3Ni2 alloy steel was composed of the grain boundary allotriomorphic ferrite/granular bainite (FGBA/BG), which the average hardness was 379HV. The phases of 30Cr3Ni2 alloy steel were mainly composed of $\alpha$-Fe solid solution, M7C3 and $\gamma$-Fe. This study paves the way for the further deepening of the research on alloy steel parts prepared by laser direct deposition.

1. Introduction

Laser direct deposition technology has been widely used in various fields with the characteristics of shaping fast and free without die, near net forming, manufacturing integration and low cost short process and so on [1-3]. Traditional technology needs to be replaced to prepare nuclear emergency diesel generator crankshaft, and new components need to be designed to accommodate laser direct deposition.

As one of the main constituent phases in steels, the formation mechanism of granular bainite have been well discussed. Z. Qiao and Y. Zhou’s [4, 5] research results have shown that the bainitic ferrite matrix in the granular bainite exists in two forms: laths and polygons. P. Xu’s study has shown that this polygonal bainitic ferrite can be called the grain boundary allotriomorphic ferrite. Compared with the single granular bainite, the FGBA/BG duplex microstructure has a better strength and toughness matching [6].

The aim of this study was to design a new type of alloy steel powder suitable for laser direct deposition. It is expected to obtain fine granular bainite microstructure with good formability, no cracks and high hardness, which can meet the performance requirements of nuclear emergency diesel generator crankshaft and enrich theoretical study on the method of preparing alloy steel parts by the laser direct deposition technology.

2. Experimental Materials and Methods

2.1 Materials and methods of the samples preparation

Table 1 is the chemical composition of 30Cr3Ni2 alloy powder and the mean partial diameter of 30Cr3Ni2 alloy powder is 200um. In this experiment, the 30Cr3Ni2 alloy steel sample was prepared under protection of argon gas in 0.2Mpa by the FL-Dlight02-3000W semiconductor laser, the spot of laser is 4.0mm×4.0mm. The laser power is 2000W, defocusing amount is 4mm, scanning speed is 8mm/s, overlapping rate is 30%. Using the powder preplaced method, the thickness of each layer of
powder is 1mm.

2.2 Experimental analysis
The alloy steel sample prepared by laser direct deposition was corroded by 4% nitric acid alcohol. The characterization of the microstructure of the sample was carried out using an optical microscope (OM, OLMPUS-GX71) and scanning electron microscope (SEM, JSM-6510A) with an EDS analyzer and a transmission electron microscope (TEM, TECNAIG220). The phase identification of the sample was performed using an X-ray diffractiometer (XRD, PW3040/60) with Cu-Kα radiation angle between 20°-100° (Vs=2°/min, U=40KV, I=200mA). The hardness data taken on the vertical sections of the sample was collected in a WILSON-WOLPER-450SVD microhardness tester at a load of 200N and an indentation time of 10s.

3. Results and discussion
3.1 Microstructure of 30Cr3Ni2 alloy steel
Fig. 1 is the cross-section OM metallograph of 30Cr3Ni2 alloy steel in which typical columnar crystals and equiaxed grains can be clearly observed without cracks and pores. As we can see, there are more columnar crystals in the bottom area of the sample where near the junction. Correspondingly, the number of equiaxed grains in central region of the sample is more. This is because of the large temperature gradient at the beginning of the direct laser deposition process, which tends to lead to the formation of columnar crystals. As the deposition process progresses, the temperature gradient decreases and more equiaxed grains are formed by thermal cycling and heat accumulation.

![Fig. 1](image)

Fig. 1 The cross-section OM metallograph of 30Cr3Ni2 alloy steel by laser direct deposition (a)-bottom region of the sample; (b)-central region of the sample.

Fig. 2 shows the SEM and EDS of 30Cr3Ni2 alloy steel by laser direct deposition. The phase composition of deposited sample is mainly granular bainite. As shown in Figure 3a, the M/A islands are granulated on the massive ferrite, and the FGBA/BG duplex microstructure can be clearly observed. According to the spot-scan analysis results shown in Table 2, the contents of C, Cr and Fe are high in the particle marked in Fig. 2(b) These elements are the main elements of the composition of M7C3, which indicates that the particle with a diameter of 1 μm is a carbide particle.
Fig. 3 shows the results of TEM observation of the 30Cr3Ni2 alloy steel sample. The selected area diffraction patterns (SADP) of the areas marked in Fig. 3 determine the presence of retained austenite and carbides in 30Cr3Ni2 alloy steel. The black areas as indicated by the arrow in Fig. 3(a) are M/A islands, and the zone axis is [1-1-1]. There is a carbide particle with a diameter of 1 μm as shown in Fig. 3(b), and the [21-3] zone axis corresponds to the M7C3 type carbide.

Fig. 4 shows the XRD analysis of 30Cr3Ni2 alloy steel by laser direct deposition. The diffraction peaks show that the grain structures of the 30Cr3Ni2 alloy steel sample are Fe-Cr-Ni solid solution, M7C3 and γ-Fe. This result is consistent with the observations of the micrographs shown above.

demonstrating that a small amount of retained austenite is present in the sample, and the circular
particles marked in Fig. 2(b) and Fig. 3(b) are M7C3 particles.

3.2 Hardness of 30Cr3Ni2 alloy steel

Fig. 5 is the hardness curve of 30Cr3Ni2 alloy steel by laser direct deposition. The relatively
stable curve corresponds to dense microstructures without cracks and pores. The curve can be
distinguished into three parts. The part I is the area near the surface of the sample, the average
hardness can be up to 500 HV. This is due to the rapid cooling rate at the near surface of the sample
results in the formation of some number of martensite. Then the martensite was tempered and
transformed into tempered martensite when heated by the next layer added on top of it, which is
equivalent to the tempering process; The part II is the central region of the sample with a BG
microstructure corresponds to Fig. 2 and its average hardness can reach 379 HV; The hardness
curve is significantly reduced when it passes through the heat affected zone to the substrate, and the
average hardness is 198 HV in the part III, which is obviously lower than that of part II.

4. Conclusions

The 30Cr3Ni2 alloy steel sample was successfully prepared by laser direct deposition without
Cracks and pores. The phase structures of 30Cr3Ni2 alloy steel are Fe-Cr-Ni solid solution, M7C3
type carbides and γ-Fe, and the size of M7C3 carbide particles are 1μm. The average hardness of the
BG microstructure in 30Cr3Ni2 alloy steel is 379 HV.
